Abstract

This paper gives the full analytical solution of the generic set of ordinary differential equations that define one-compartment toxicokinetic models. These models describe the uptake and elimination processes that occur within living organisms when exposed to chemical substances. The models solved in this paper consider living organisms as a unique compartment, into which a parent compound enters via several possible exposure routes and from which it is eliminated as well as its potential metabolites. Benefiting from generic solutions of one-compartment toxicokinetic models is particularly useful when fitting them to experimental data, facilitating the writing of the inference algorithms leading to parameter estimates. Additionally, these models are of crucial interest in environmental risk assessment for the calculation of bioaccumulation metrics as required by regulators in support of decision-making when they evaluate dossiers for marketing authorisation of active substances.

Introduction

In this paper, we consider a generic one-compartment toxicokinetic (TK) model describing uptake and elimination processes within living organisms when exposed to chemical substances. From a general point-of-view, the term TK refers to the movement and fate (also called disposition) of chemical substances that are potentially toxic. In particular, this term is used when describing the time course of absorption, distribution and elimination (accounting for both biotransformation and excretion) of substances within organisms (ADME). Toxicokinetics is also related to pharmacokinetics and is often considered as the same scientific field, the main difference being linked to the type of compound (toxicants or pharmaceuticals). In comparison with pharmaceutical exposure, exposure to toxicants is often uncontrolled and variable over time predominantly at larger concentrations.[1]

Mathematical TK models are particularly useful to predict the adverse effects of xenobiotics or to prevent undesired residues within animal tissues from entering the human food chain.[2] Indeed, TK models allow the prediction of tissue concentrations over time, involving several kinetic parameters, such as uptake and elimination rates, from which useful metrics for assessing risk may be derived.[3] Additionally, TK models can be used to facilitate a better understanding of the underlying physiological mechanisms driving chemical ADME processes.[4,5]

A wide variety of TK models exists, chosen from both the available data and the use intended for the model (e.g., describe and/or predict); simple or more complex models may be preferred accordingly.[6] Basically, we distinguish classic TK models from physiologically-based (PB) TK models, referred to as PBTK, or PBPK (standing for PB Pharmaco-Kinetic) models in the field of pharmacology. As fully detailed in Gehring *et al.*,[7] PBPK models are a crucial tool in Environmental Risk Assessment (ERA) for regulatory bodies, such as the US Environmental Protection Agency (US EPA) and European Food Safety Authority (EFSA).[8,9] In fact, PBPK models are an ethical and scientifically sound method to predict exposure to toxic xenobiotics in humans through animal-to-human extrapolation or based on human biomonitoring data. (PB)TK models are also of particular interest for ERA, when the calculation of bioaccumulation metrics is required by regulators to evaluate dossiers for substance marketing authorizations.[10–12]

The generic TK model we unravel in this paper is a one-compartment model that considers organisms as a whole, in which chemical compounds may enter and from which these compounds can be eliminated. More complex TK models (namely PBTK models) refine the description of contamination pathways within organisms, distinguishing organs and tissues from physiological hypotheses on potential targets of exposure compounds; PBTK models have been

Table 1. Symbols, meaning, and units of all parameters and variables involved in the full set of ordinary differential equations defining the generic one-compartment toxicokinetic model

Symbol	Meaning and unit
t	time (in time units)
t_c	duration of the accumulation phase (in time units)
$C_p(t)$	internal concentration of the parent compound at t (in $\mu g \cdot g^{-1}$)
$C_{m_\ell}(t)$	internal concentration of metabolite ℓ at t (in $\mu g \cdot g^{-1}$)
$U = \sum_{i=1}^{I} k_{u_i} c_i$	sum of all uptake terms
c_i	concentration via the exposure route i (in $\mu g \cdot mL^{-1}$)
$E = \sum_{j=1}^{J} k_{e_j}$	sum of all elimination terms for the parent compound
$M = \sum_{\ell=1}^{L} k_{m_\ell}$	sum of all elimination terms for metabolite ℓ
i	index of exposure sources, $i = 1...I$
j	index of elimination processes, $j = 1...J$
ℓ	index of metabolites, $\ell = 1...L$
I	total number of exposure sources (#)
J	total number of elimination processes (#)
L	total number of metabolites (#)
k_{u_i}	uptake rate of exposure source i (per time units)
k_{e_j}	excretion rates of elimination process j (per time units)
k_{e_ℓ}	excretion rates of metabolite ℓ (per time units)
k_{m_ℓ}	metabolization rate of metabolite ℓ (per time units)
$R = \dfrac{U}{E + M}$	NA
$D_\ell = k_{e_\ell} - (E + M)$	NA, $\forall \ell = 1...L$
$Q = C_0 - R\left(1 - e^{(E+M)t_c}\right)$	NA

stands for numbers, while NA means 'Not Applicable'

mainly developed for humans[13,14] and big mammals.[15,16] Recently, a PBTK model was proposed by Gestin *et al.*[17] for invertebrates, pushing the immense potential of these models a step further.

Our TK model, even if not fully refined as a PBTK model, has the great advantage of accounting for several exposure sources (*e.g.*, water, sediment, and/or food), several elimination processes (*e.g.*, direct elimination, dilution by growth and/or biotransformation), and several potential metabolites of the parent chemical compound to which organisms are exposed.[18] The next section details the dynamic system of ordinary differential equations (ODEs) and the mathematical exact solution, followed by a summary of the full set of ODE in section 3. Then, section 4 illustrates the use of model based on simulations from parameter values obtained by the study of real datasets.

One-compartment TK set of ODE

Our generic one-compartment TK model is composed of two sets of ODE: accumulation and depuration sets. The accumulation phase includes both absorption and elimination processes, as those related to the biotransformation of the parent compound into metabolites, during which organisms are exposed to a given compound. The depuration phase concerns only elimination processes, including biotransformation, during which organisms are transferred into a clean medium. The transition from one set of ODE to the other takes place at time t_c corresponding to the duration of the accumulation phase (see Table 1).

In practice, the exposure concentration to which organisms are exposed may vary over time in real environments. This means

there is no analytical solution of the TK model, so that only a numerical solution can be obtained with an appropriate algorithm. Therefore, our work assumes that the exposure concentration remains constant over time regardless of the exposure source. Such an experimental condition can be ensured for most chemical compounds when performing laboratory experiments. In addition, this assumption provides the exact solution of the full one-compartment TK model by considering as many routes of exposure and as many elimination processes as desired, as well as an infinite number of phase I metabolites, *i.e.*, directly derived from the parent compound to which organisms are exposed. Kuo *et al.*[19] previously suggested a partially resolved one-compartment TK model but only for the accumulation phase and one exposure route. In a similar manner, D'Argenio *et al.*[12] published an analytical solution for a linear multi-compartments TK model with a non-zero initial condition.

Accumulation phase ($0 \leq t \leq t_c$)

The set of ODEs describing the accumulation phase ($0 \leq t \leq t_c$) is as follows:

$$
\begin{cases}
\dfrac{dC_p(t)}{dt} = U - (E + M) \times C_p(t) & \text{(a)} \\[2mm]
\dfrac{dC_{m\ell}(t)}{dt} = k_{m\ell} \times C_p(t) - k_{e\ell} \times C_{m\ell}(t), \forall \ell = 1 \cdots L & \text{(b)}
\end{cases} \quad (1)
$$

All parameters and variables, with their meaning and units when applicable, are provided together in Table 1.

Equation (1.a) for the parent compound is a linear first-order ODE with constant coefficients and a second member. Equation (1.a) admits $C_{part}(t) = \dfrac{U}{E+M} = R$ as a particular solution. Equation (1.a) without its second member is:

$$
\frac{dC_p(t)}{dt} - (E + M) \times C_p(t) = 0 \Leftrightarrow C_p(t) = K \times e^{-(E+M) \times t}, K \in \mathbb{R}^+ \quad (2)
$$

Given the initial condition $C(t = 0) = C_0$ ($C_0 \geq 0$), we can obtain the full analytical solution of Equation (1.a), providing that the internal concentration of the parent compound over time during the accumulation phase ($0 \leq t \leq t_c$) is as follows:

$$
C_p(t) = (C_0 - R) \times e^{-(E+M) \times t} + R \quad (3)
$$

See Table 1 for the definition of parameter R.

Equation (1.b) is also a linear first-order ODE with constant coefficients and a second member, with the following analytical solution when the second member is removed:

$$
\frac{dC_{m\ell}(t)}{dt} - k_{e\ell} \times C_{m\ell}(t) = 0 \Leftrightarrow C_{m\ell}(t) = K \times e^{-k_{e\ell} \times t}, K \in \mathbb{R}^+, \forall \ell = 1 \ldots L \quad (4)
$$

The method of variation of a constant consists of writing the general solution of Equation (1.b) as:

$$
C_{m\ell}(t) = K(t) \times e^{-k_{e\ell} \times t} \quad (5)
$$

which is used to find function $K(t)$ by deriving $C_{m\ell}(t)$ then insert the result into Equation (5). The derivative of Equation (1.b) then becomes:

$$
\frac{dC_{m\ell}(t)}{dt} = \frac{dK(t)}{dt} \times e^{-k_{e\ell} \times t} - K(t) \times k_{e\ell} \times e^{-k_{e\ell} \times t} \quad (6)
$$

Inserting the result from the previous equation into Equation (1.b) leads to:

$$
\frac{dK(t)}{dt} = k_{m\ell} \times \left((C_0 - R) \times e^{D_\ell \times t} + R \times e^{k_{e\ell} \times t} \right) \quad (7)
$$

which integrates into:

$$
K(t) = k_{m\ell} \times \left(\frac{C_0 - R}{D_\ell} \times e^{D_\ell \times t} + \frac{R}{k_{e\ell}} \times e^{k_{e\ell} \times t} \right) + C, C \in \mathbb{R} \quad (8)
$$

See Table 1 for the definition of parameter D_ℓ.
The general solution of Equation (1.b) finally becomes:

$$
C_{m\ell}(t) = k_{m\ell} \times \left(\frac{C_0 - R}{D_\ell} \times e^{-(E+M) \times t} + \frac{R}{k_{e\ell}} \right) + C \times e^{-k_{e\ell} \times t}, C \in \mathbb{R} \quad (9)
$$

When considering the initial condition $C_{m_\ell}(t = 0) = 0$ when the accumulation phase starts, organisms are only exposed to the parent compound, so that there are no metabolites. With this condition, we can finally acquire the full analytical solution of Equation (1.b), providing the internal concentration of metabolite ℓ over time during the accumulation phase:

$$
C_{m_\ell}(t) = k_{m_\ell} \times \left\{ \frac{C_0 - R}{D_\ell} \times \left(e^{-(E+M) \times t} - e^{-k_{e_\ell} \times t} \right) \right.
$$
$$
\left. + \frac{R}{k_{e_\ell}} \times \left(1 - e^{-k_{e_\ell} \times t} \right) \right\} \quad (10)
$$

Depuration phase ($t > t_c$)

The set of ODEs describing the depuration phase ($t > t_c$) is as follows:

$$
\begin{cases}
\dfrac{dC_p(t)}{dt} = -(E + M) \times C_p(t) & \text{(a)} \\[2mm]
\dfrac{dC_{m\ell}(t)}{dt} = k_{m\ell} \times C_p(t) - k_{e\ell} \times C_{m\ell}(t), \forall \ell = 1 \cdots L & \text{(b)}
\end{cases} \quad (11)
$$

The definitions and units (when applicable) of the parameters and variables are described together in Table 1.

Equation (11.a) is a linear first-order ODE without a second member, so that it has a general solution of the following form:

$$
C_p(t) = K \times e^{-(E+M) \times t}, K \in \mathbb{R}^+ \quad (12)
$$

For the depuration phase and the parent compound, the initial condition comes from the calculation of the internal parent compound concentration at the end of the accumulation phase (*i.e.*, at time $t = t_c$) using Equation (13):

$$
C_p(t_c) = (C_0 - R) \times e^{-(E+M) \times t_c} + R \quad (13)
$$

From the general analytical solution given by Equation (12), we get $C_p(t_c) = Ke^{-(E+M)t_c}$, from which constant K in Equation (12) is determined by:

$$
K = C_0 - R + R \times e^{(E+M) \times t_c} \quad (14)
$$

Then, the final analytical solution of Equation (11.a), providing the internal concentration of the parent compound over time during the depuration phase ($t > t_c$), becomes:

$$C_p(t) = \left(C_0 - R \times \left(1 - e^{(E+M)\times t_c}\right)\right) \times e^{-(E+M)\times t} \qquad (15)$$

For simplicity reasons, Equation (15) can be written as $C_p(t) = Qe^{-(E+M)\times t}$, where Q is defined in Table 1.

Equation (11.b) is a linear first-order ODE with constant coefficients and a second member. The analytical solution of Equation (11.b) without its second member is:

$$C_{m_\ell}(t) = K \times e^{-k_{e_\ell}\times t}, K \in \mathbb{R}^+ \qquad (16)$$

As previously stated, the method of the variation of a constant provides the general solution of Equation (11.b) as $C_{m_\ell}(t) = K(t)e^{-k_{e_\ell}t}$, from which function $K(t)$ must be determined.

The derivative of $C_{m_\ell}(t)$ from Equation (16) is:

$$\frac{dK(t)}{dt} = e^{-k_{e_\ell}\times t} - k_{e_\ell} \times K(t) \times e^{-k_{e_\ell}\times t} \qquad (17)$$

Inserting Equation (17) into Equation (11.b) leads to:

$$\frac{dK(t)}{dt} = k_{m_\ell} \times Q \times e^{D_\ell \times t} \qquad (18)$$

which integrates into:

$$K(t) = k_{m_\ell} \times \frac{Q}{D_\ell} \times e^{D_\ell \times t} + C, C \in \mathbb{R} \qquad (19)$$

finally leading to the general analytical solution of Equation (11.b):

$$C_{m_\ell}(t) = k_{m_\ell} \times \frac{Q}{D_\ell} \times e^{-(E+M)\times t} + C \times e^{-k_{e_\ell}\times t}, C \in \mathbb{R} \qquad (20)$$

Constant C can be determined from the initial condition, *i.e.*, from the internal concentration of metabolite ℓ at $t = t_c$ both at the end of the accumulation phase and at the beginning of the depuration phase. From Equation (20), we get $C_{m_\ell}(t_c) = k_{m_\ell}\frac{Q}{D_\ell}e^{-(E+M)t_c} + Ce^{-k_{e_\ell}t_c}$, and from Equation (10), we obtain $C_{m_\ell}(t_c) = k_{m_\ell}\left[\frac{C_0-R}{D_\ell}\left(e^{-(E+M)t_c} - e^{-k_{e_\ell}t_c}\right) + \frac{R}{k_{e_\ell}}\left(1 - e^{-k_{e_\ell}t_c}\right)\right]$.
Finally, the expression for constant C can be determined using:

$$C = k_{m_\ell} \times \left(\frac{R}{k_{e_\ell}} \times \left(e^{k_{e_\ell}\times t_c} - 1\right) - \frac{C_0 - R}{D_\ell} - \frac{R}{D_\ell} \times e^{k_{e_\ell}\times t_c}\right) \qquad (21)$$

Replacing constant C in Equation (20) gives the final analytical solution of Equation (11.b), which yields the internal concentration of metabolite ℓ for the depuration phase ($t > t_c$) as follows:

$$C_{m_\ell}(t) = k_{m_\ell} \times \left(\frac{Q}{D_\ell} \times e^{-(E+M)\times t} + \frac{R}{k_{e_\ell}} \times \left(e^{-k_{e_\ell}\times(t-t_c)} - e^{-k_{e_\ell}\times t}\right)\right.$$
$$\left. - \frac{C_0-R}{D_\ell} \times e^{-k_{e_\ell}\times t} - \frac{R}{D_\ell} \times e^{-k_{e_\ell}\times(t-t_c)}\right) \qquad (22)$$

Replacing constant Q by its own expression (Table 1) leads to:

$$C_{m_\ell}(t) = k_{m_\ell} \times \left(\frac{C_0-R}{D_\ell} \times \left(e^{-(E+M)\times t} - e^{-k_{e_\ell}\times t}\right)\right.$$
$$+ \frac{R}{k_{e_\ell}} \times \left(e^{-k_{e_\ell}\times(t-t_c)} - e^{-k_{e_\ell}\times t}\right)$$
$$\left. + \frac{R}{D_\ell} \times \left(e^{-(E+M)\times(t-t_c)} - e^{-k_{e_\ell}\times(t-t_c)}\right)\right) \qquad (23)$$

Generic set of solutions

Considering the following intermediate notations $R = \frac{U}{E+M}$ and $D_\ell = k_{e_\ell} - (E + M)$, we can obtain the full set of analytical solutions corresponding to the whole one-compartment TK set of ODE describing the time-course for the accumulation and depuration phases of the parent compound and its potential metabolites.

- The analytical solution for the internal concentration of the parent compound during the accumulation phase, previously referred as Equation (3), becomes:

$$C_p(t) = \left(C_0 - \frac{U}{E+M}\right) \times e^{-(E+M)\times t} + \frac{U}{E+M}, \forall 0 \leqslant t \leqslant t_c$$

- The analytical solution for the internal concentration of metabolite ℓ during the accumulation phase, previously referred as Equation (10), is:

$$C_{m_\ell}(t) = \frac{k_{m_\ell}}{k_{e_\ell}} \times \frac{U}{E+M} \times \left(1 - e^{-k_{e_\ell}\times t}\right) + \frac{k_{m_\ell}}{k_{e_\ell} - (E+M)}$$
$$\times \left(C_0 - \frac{U}{E+M}\right) \times \left(e^{-(E+M)\times t} - e^{-k_{e_\ell}\times t}\right), \forall 0 \leqslant t \leqslant t_c$$

- The analytical solution for the internal concentration of the parent compound during the depuration phase, previously referred as Equation (15), is written as:

$$C_p(t) = \left(C_0 - \frac{U}{E+M} \times \left(1 - e^{(E+M)\times t_c}\right)\right) \times e^{-(E+M)\times t}, \forall t > t_c$$

- The analytical solution for the internal concentration of metabolite ℓ during the depuration phase, previously referred as Equation (23), is determined using:

$$C_{m_\ell}(t) = \frac{k_{m_\ell}}{k_{e_\ell} - (E+M)} \times \left(C_0 - \frac{U}{E+M}\right) \times \left(e^{-(E+M)\times t} - e^{-k_{e_\ell}\times t}\right)$$
$$+ \frac{k_{m_\ell}}{k_{e_\ell}} \times \frac{U}{E+M} \times \left(e^{-k_{e_\ell}\times(t-t_c)} - e^{-k_{e_\ell}\times t}\right)$$
$$+ \frac{k_{m_\ell}}{k_{e_\ell} - (E+M)} \times \frac{U}{E+M} \times \left(e^{-(E+M)\times(t-t_c)} - e^{-k_{e_\ell}\times(t-t_c)}\right), \forall t > t_c$$

Then, the final generic analytical solution of the one-compartment TK model can be achieved to estimate all parameters from observed data using an inference process by replacing constants U, E and M with $U = \sum_{i=1}^{I} k_{u_i} \times c_i$, $E = \sum_{j=1}^{J} k_{e_j}$ and $M = \sum_{\ell=1}^{L} k_{m_\ell}$, respectively.

Model simulations based on real case-studies

Currently, the above exact mathematical solution of the generic one-compartment TK model is used in support of the development of the R-package *rbioacc*[20] as well as its web interface MOSAIC$_{bioacc}$, which is freely available at https://mosaic.univ-lyon1.fr/bioacc.[21] Both tools allow fitting the TK model to bioaccumulation data in a user-friendly way, providing all necessary outputs to check for goodness-of-fit and obtain bioaccumulation metrics, regardless of the considered species-compound combination. The database associated to the web interface is also available online at http://lbbe-shiny.univ-lyon1.fr/mosaic-bioacc/data/database/TK_database.html, with a wide collection of accumulation-depuration data in support of toxicokinetic modelling.[22]

Table 2. Sets of inputs for model simulations according to Figures 1 to 5

Input	Units	Simple (section 4.1)	Multiple exposures (section 4.2)	Biotransformation (section 4.3)

k_{e_2}	$days^{-1}$	–	–	0.123
k_{e_3}	$days^{-1}$	–	–	0.7808

(–) Hyphens stand for no required inputs.

From this database, we selected three real case-studies from which we got fitting results (especially the joint posterior probability distribution of all kinetic parameters) in order to perform the subsequent model simulations, thus illustrating the use of the generic TK model.

All model simulations of the generic set of mathematical solutions (Equations (3), (10), (15) and (23)) were performed using R software with the *rbioacc* package and function *predict*().[20] Note that the same simulations can be performed directly online with the MOSAIC*bioacc* platform and its prediction module (https://mosaic.univ-lyon1.fr/bioacc). We used 500 time points in [0; t_f], where t_f stands for the final time of each simulation. These simulations illustrate the use of the generic TK model in three case studies where different compounds are bioaccumulated by different species. In order to proceed, the time duration of the accumulation phase (parameter t_c) is required, as well as the exposure concentrations in the media and the model parameter values (Table 2); all associated numerical values were taken from fitting results performed with real data sets. Figures 1 to 5 show the simulations of internal concentrations over time for the three species-compound combinations, as subsequently described. For each case study, TK model parameters were varied one-at-a-time with 20, 50, and 80% of increase from their original value.

Elementary one-compartment TK model

Equations (3) and (15) were simulated for a simple case study in

which fish are exposed to a highly hydrophobic chemical contaminated water and only excretion is considered (Fig. 1 and Table 2).[5] The corresponding inputs are the exposure concentration c_w (referring to c_i and $I = 1$), uptake rate from water k_{u_w} (referring to k_{u_i} and $I = 1$), and excretion rate k_{e_e} (referring to k_{e_j} and $J = 1$). When parameter k_{u_w} increases, internal concentrations become higher (*e.g.*, blue curve in Fig. 1a) than with the original value (orange curve in Fig. 1a). Biologically speaking, the higher the uptake rate is for a given substance, the more it is bioaccumulated by organisms. Conversely, an increase in parameter k_{e_e} leads to a lower internal concentration (*e.g.*, blue curve in Fig. 1b), which is consistent with the known underlying biological mechanism: the faster a contaminant is eliminated, the quicker its concentration decreases in organisms.

One-compartment TK model with several exposure routes, no metabolites

Equations (3) and (15) are simulated for case, in which freshwater shrimp are exposed to an organic chlorine compound through contaminated sediment and food, and only natural excretion is considered as the elimination process (Fig. 2 and Table 2).[23] The corresponding inputs are the exposure concentration via sediment c_s and food c_f (referring to c_i and $I = 2$), the two uptake rates from sediment and food, k_{u_s} and k_{u_f} (referring to k_{u_i} and $I = 2$), and excretion rate k_{e_e} (referring to k_{e_j} and $J = 1$). When parameter k_{u_s} increases,
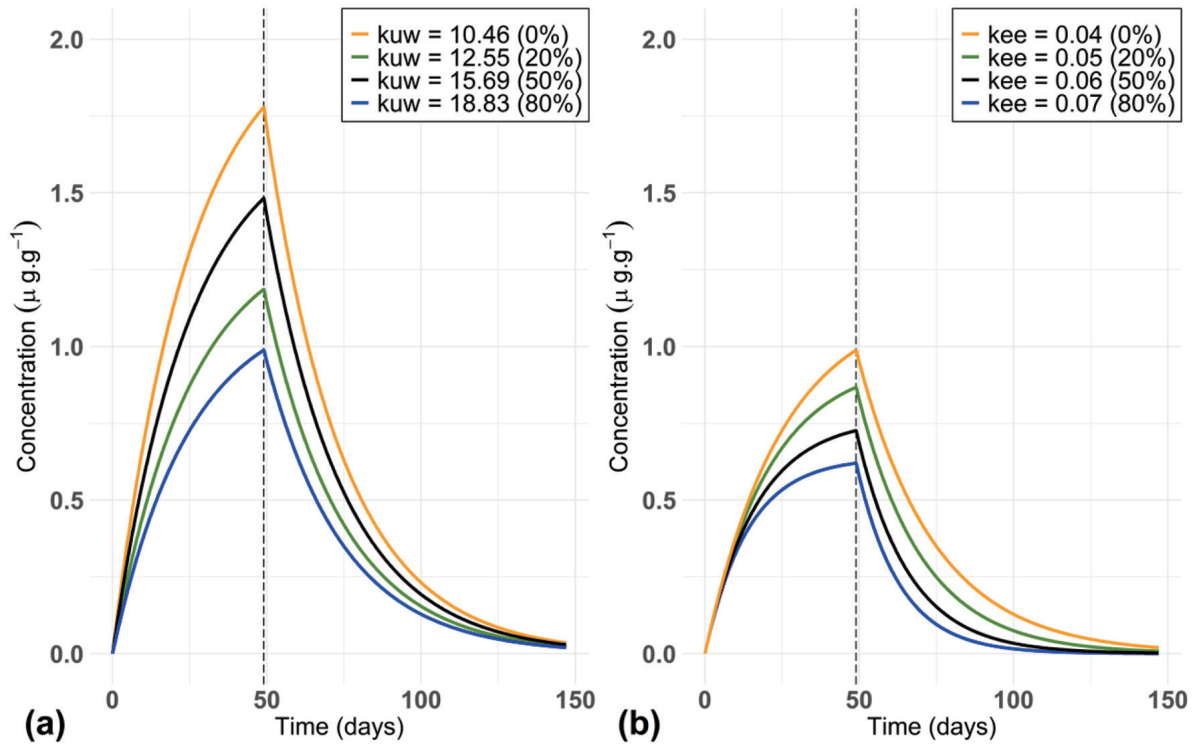

Fig. 1. Example of model simulations for a simple TK model (exposure via water and elimination by excretion) and the influence of variations of parameters (a) k_{u_w} **(uptake rate) and (b)** k_{e_e} **(excretion rate).** TK, toxicokinetic.

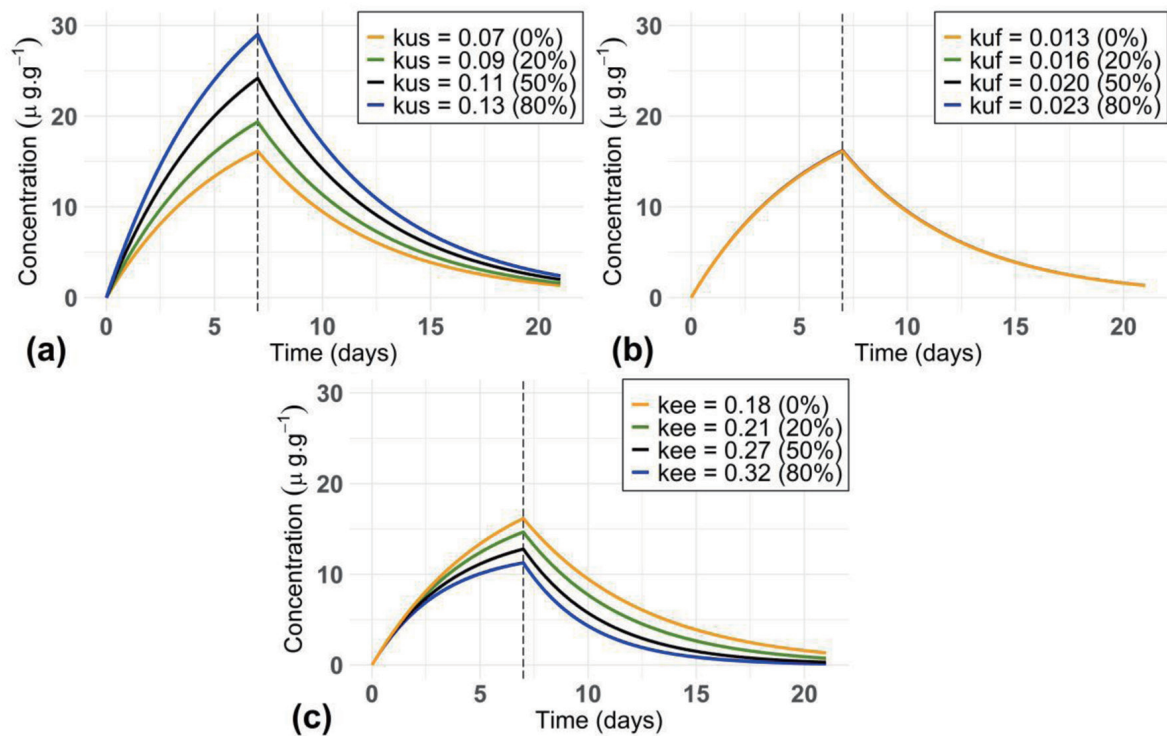

Fig. 2. Example of model simulations for a TK model with multiple exposure routes (via sediment and food) and influence of variations of parameters (a) k_{u_s} **(uptake rate from sediment), (b)** k_{u_f} **(uptake rate from food) and (c)** k_{e_e} **(excretion rate).** TK, toxicokinetic.
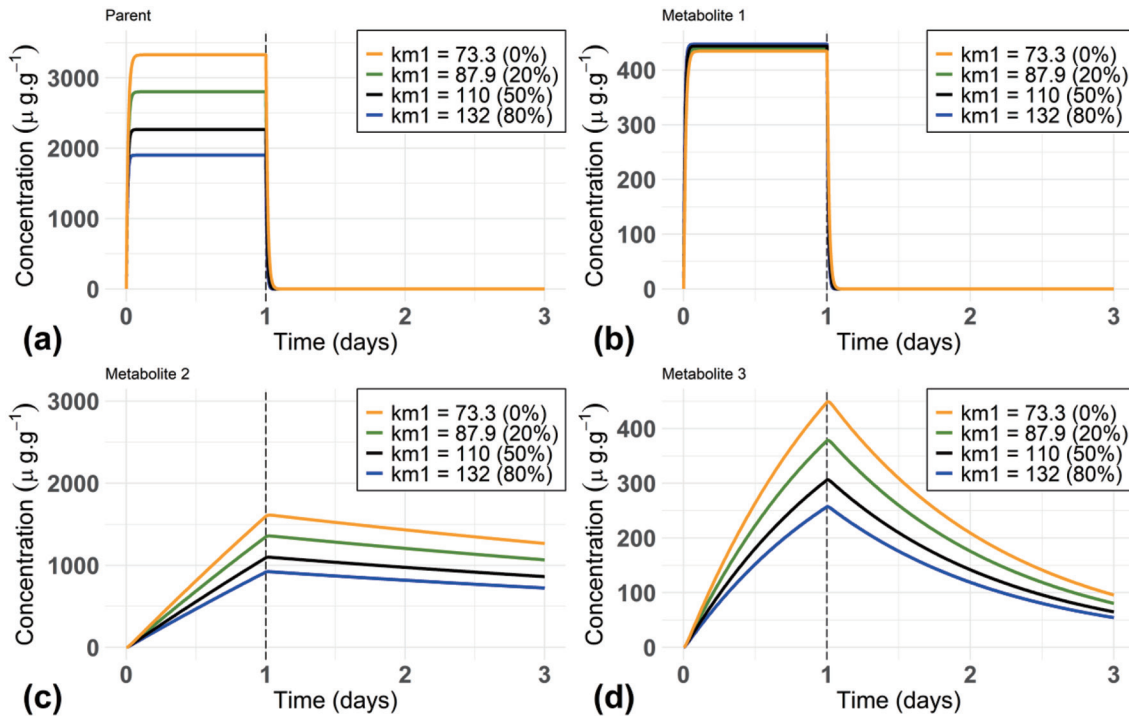

Fig. 3. Example of model simulations for a TK model with biotransformation (three metabolites) and influence of the variations of parameter k_{m_1} (bio-transformation rate for metabolite 1) on (a) the parent compound, (b) metabolite 1, (c) metabolite 2, and (d) metabolite 3. TK, toxicokinetic.

internal concentrations are higher (*e.g.*, blue curve in Fig. 2a) than with the original value (orange curve in Fig. 2a). Biologically, the higher the uptake rate from sediment is for a given substance, the stronger it is bioaccumulated by organisms. Regarding the exposure from food, as parameter k_{u_f} is low in this case, its variation has minimal influence on the internal concentration of the contaminant (Fig. 2b). This means that the exposure via sediment is the major route of contamination for these organisms. Besides, as previously shown in section 4.1, an increase in parameter k_{e_e} leads to a faster decreasing concentration (*e.g.*, blue curve in Fig. 2c).

One-compartment TK model with one exposure route, several metabolites

Equations (3), (10), (15) and (23) are simulated for case, in which freshwater shrimp are exposed to an organic biocide by contaminated water. Three metabolites derived from the parent compound are considered[24] together with the natural excretion (Figs. 3 to 5 and Table 2). The corresponding inputs are the exposure concentration via water c_w (referring to c_i and $I = 1$), the uptake rate k_{u_w} (referring to k_{u_i} and $I = 1$), excretion rate k_{e_e} (referring to k_{e_j} and $J = 1$), three metabolization rates k_{m_1}, k_{m_2} and k_{m_3} (referring to k_{m_ℓ} and $L = 3$), and three elimination rates of the metabolites k_{e_1}, k_{e_2} and k_{e_3} (referring to to k_{e_ℓ} and $L = 3$). When parameter k_{m_1} increases, internal concentrations of metabolite 1 increase (*e.g.*, blue curve in Fig. 3b) greater than with the original value (orange curve in Fig. 3b). Conversely, internal concentrations are lower for the parent compound (*e.g.*, blue curve in Fig. 3a). In other words, the more the biotransformation rate for a given metabolite increases, the higher its concentration becomes within organisms due to the highly biotransformation of the parent compound. This leads to a lower internal concentration of the parent compound than with the

original value of k_{m_1} (*e.g.*, blue curve, Fig. 3a). An increase in k_{m_1} also induces a decrease in the internal concentrations of the other metabolites (Figs. 3c and d). Besides, an increase in parameter k_{e_1} only affects the internal concentration of metabolite 1 (Fig. 4b). In addition, as previously viewed (sections 4.1 and 4.2), an increase in parameter k_{u_w} will induce high internal concentrations for both the parent compound and its metabolites (Fig. 5). Indeed, the more the internal concentration of the parent compound increases, the more the biotransformation process will intensify, leading to high internal concentrations for each metabolite.

Future directions

Based on the results of this work, we suggest future research aims to acquire a better understanding of the variation of TK parameters according to the chemicals and their exposure concentrations in the environment. In particular, the influence of concentration dependency may be investigated through the TK parameter values. For example, if the uptake rate remains on the same order of magnitude rather than increasing two-fold when the exposure concentration doubles, this would most likely indicate a concentration dependency. A second interesting research direction would be the elaboration of an improved modelling framework that includes phase II metabolites within the TK model; some experimental data are already available to support such research but no model exists yet.

Conclusions

As supported by complete mathematical and exact calculations, our work introduces a practical and generic one-compartment TK
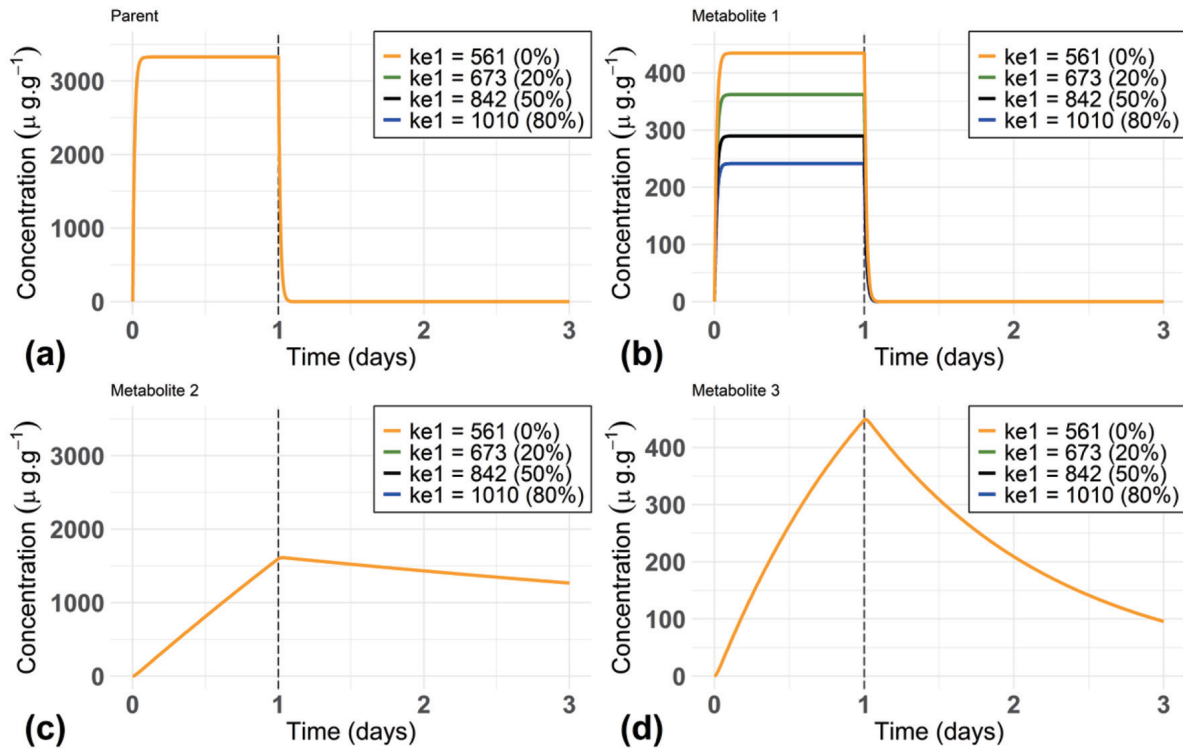

Fig. 4. Example of model simulations for a TK model with biotransformation (three metabolites) and influence of the variations of parameter k_{e_1} (elimination rate of metabolite 1) on (a) the parent compound, (b) metabolite 1, (c) metabolite 2, and (d) metabolite 3. TK, toxicokinetic.

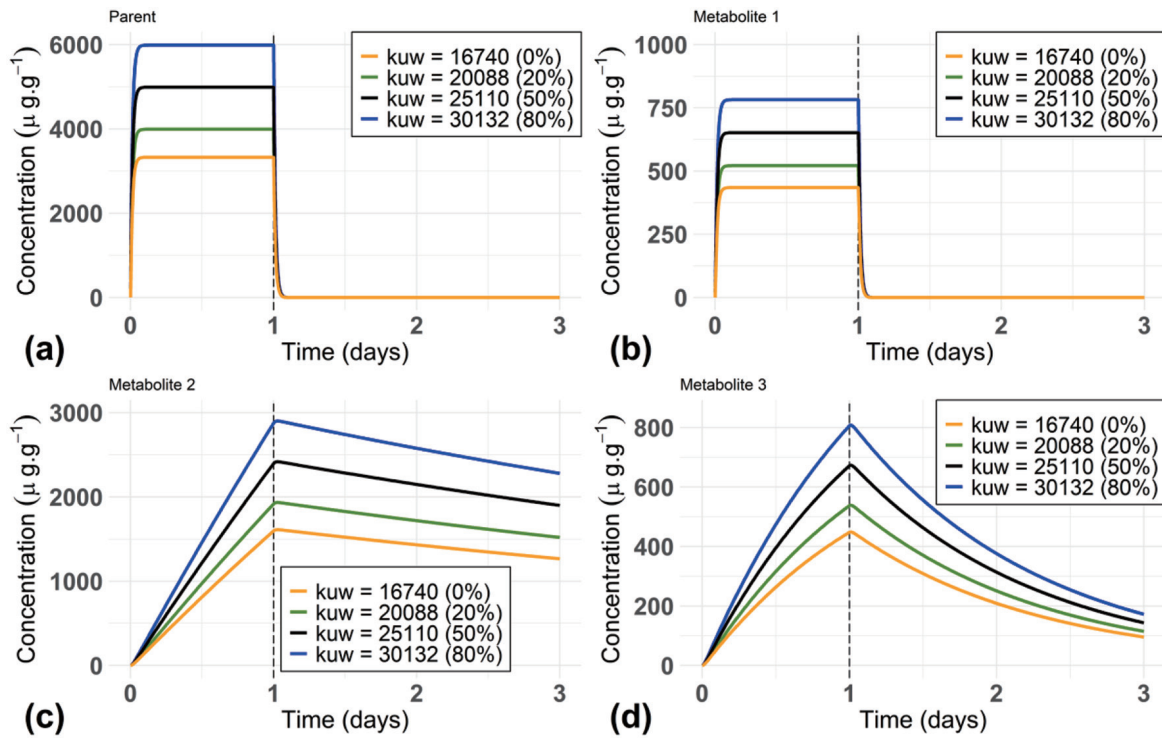

Fig. 5. Example of model simulations for a TK model with biotransformation (three metabolites) and influence of the variations of parameter k_{u_w} on (a) the parent compound, (b) metabolite 1, (c) metabolite 2, and (d) metabolite 3. TK, toxicokinetic.

model to deal with different species-compound combinations of interest. To-date, such a model is required by regulatory bodies to perform risk assessment of chemical substances. The generic feature of this model is, thus, in full compliance with the numerous situations that regulators are expected to be faced. The associated ready-to-use tools we developed to perform different actions, including calibration of experimental data, validation of simulations compared to observed data, and predictions in untested situations, should be of pertinent use to such regulators.

Conflict of interest

The authors have no conflicts of interest related to this publication.

Author contributions

Contributed to study concept and design (SC, AR and CL), generic solving (SC, CL), acquisition of the data (AR), assay model simulations (AR), drafting of the manuscript (SC, AR and CL), supervision (SC, CL).

Data sharing statement
